## Investigation of instruments for real-time suspended sediment monitoring

Many rivers transport fine sediment particles in suspension (Fig. 1). This is ecologically relevant and needs to be considered in the sustainable operation of hydropower plants, e.g. with respect to reservoir sedimentation and turbine erosion. Real-time data on suspended sediment concentration (SSC) and particle size distribution (PSD) are required for a better understanding of such processes and as a basis for improved sediment management. Various measuring techniques are available: turbidimetry, acoustic backscatter (ABS), densimetry and laser diffraction (LISST). The latter is currently the only real-time in-situ technique yielding both SSC and PSD with high temporal resolution and in detailed size classes.

As a basis for a field study, the performances of such instruments (e.g. an acoustic sensor in Fig. 2) shall be investigated in the hydraulic laboratory. Therefore, measurements on sediment-laden water at increasing SSC will be carried out using these instruments and reference methods. The measurements will be evaluated to establish or improve the calibration of the instruments for specific particle types and to quantify the measuring uncertainties. Based on the findings, the possibilities and limitations for the use of the instruments in field conditions shall be addressed.

This investigation allows you to get to know most of the state-of-the-art methods for real-time suspended sediment monitoring and improve your skills for experimental investigations and data evaluation.
