# Lecture 3

## **Surfactant Science**

The functional chemical components inside detergents are the surfactants, which remove oil from dishes and dirt from clothes. The term *surfactant* is short for *surface active agent*<sup>1</sup> that "activates" the surface by reducing the surface / interfacial tension. In this lecture we will see the chemistry and physics behind the surfactant science.

### 3.1 Basic mechanism of surfactants

Surfactants are a large group of **amphiphilic** molecules which contains both hydrophobic and hydrophilic groups. Commercially available surfactants usually have a hydrophilic "head" (e.g. small polar or charged group, like -OH, -COOH, -CN,  $-SO_3^-$ ,  $-OSO_3^-$ , etc.) and a hydrophobic "tail" (e.g. long hydrocarbon chains). The typical structure of a surfactant can be seen in Figure 3.1.

Figure 3.1: Scheme of surfactants and the interfacial behavior. Left: chemical structure of a typical industrial surfactant, sodium dodecyl sulfate (SDS), which consists of a hydrophilic head and a hydrophobic tail. Right: assembly of surfactants on the water-air interface. The hydrophilic heads are embedded in water and tails are in air.

The interaction work  $\Delta W_{hw}$  between the head and water is usually larger than  $\Delta W_{tw}$  between the tail and water. Due to the large portion of tail, the energy of dissolving a surfactant molecule in bulk water is larger than putting the surfactant at the water surface.

At the water-air interface, the surfactants tend to have the heads towards water molecules, and the tails toward air (Figure 3.1). Experimentally, it is observed that the water surface tension  $\gamma_w$  of the surfactant solution varies with the surfactant concentration *c*. By adding surfactants,  $\gamma_w$  drops from the surface tension of pure water  $\gamma_{L,0}$ , before *c* reaches a critical concentration  $c_{\text{CMC}}$  (Figure 3.2). When  $c > c_{\text{CMC}}$ ,  $\gamma_w$  no longer decreases with further addition of surfactants. The concentration  $c_{\text{CMC}}$  is called the **critical micelle concentration** (CMC).

Figure 3.2: Simulated Water surface tension  $\gamma_w$  as a function of surfactant concentration c. When  $c < c_{CMC}$ ,  $\gamma_w$  decreases with adding surfactants, due to incomplete coverage of surfactants. When  $c > c_{CMC}$ ,  $\gamma_w$  remains constant and micelles form.

The behavior of  $\gamma_w$  with *c* is related to the microscopic picture of surfactants in water. When  $c < c_{CMC}$ , surface coverage of surfactants is incomplete. Additional surfactants will first occupy the water-air interface and  $\gamma_w$  gradually decreases. When  $c_{CMC}$  is reached, the surface area is fully covered by the surfactants, and extra surfactants will only form micelles in bulk water (see insets of Figure 3.2). Therefore when  $c > c_{CMC}$ ,  $\gamma_w$  saturates. A micelle is the aggregate of surfactants in bulk solution, that hydrophilic heads are towards water molecules and the hydrophobic tails are embedded inside.<sup>2</sup>

So how do surfactants in detergents function? From our simple picture in Lecture 1, the interfacial tension  $\gamma_{wo}$  between water and oil can be approximated by  $\gamma_{wo} = (\sqrt{\gamma_w} - \sqrt{\gamma_o})^2$ . Therefore if  $\gamma_w$  becomes smaller by adding surfactants,  $\gamma_{wo}$  also decreases. Consider an oil droplet on cloth that immersed in water (Figure 3.3a), the total surface energy is:

$$E_{\rm c} = \gamma_{\rm wc} f A_{\rm c} + \gamma_{\rm oc} (1 - f) A_{\rm c} + \gamma_{\rm wo} A_{\rm o}$$

$$(3.1)$$

where  $\gamma_{wc} \approx \gamma_w$  is the interfacial tension between water and cloth,  $A_c$  is the total area of the cloth, f is the fraction of unstained surface on the cloth,  $\gamma_{oc}$  is the interfacial tension

#### 3.2. ADSORPTION AND SURFACE TENSION

between oil and cloth, and  $A_o$  is the contact area between water and oil. When  $c < c_{CMC}$ ,  $\gamma_w$  and  $\gamma_{wc}$  gradually drops. which makes it easier to release the oil droplet from the cloth (Figure 3.3b). Increasing *c* (but not larger than  $C_{CMC}$ ) improves the cleaning ability. When  $c > c_{CMC}$ , the cleaning ability of the surfactant does not further increase, since  $\gamma_w$  saturates. However, the capacity of the detergent (the amount of oil stabilized in water) becomes higher due to the formation of micelles which can stabilize more oil droplets in water (Figure 3.3c).

Figure 3.3: The mechanism of surfactants in detergent. (a) A droplet of oil on cloth that immersed in water. The oil droplet adheres to the cloth surface due to relatively low  $\gamma_{oc}$ . (b) Same with (a) but immersed in surfactant solution at cmc, the surfactants assemble at the oil-water interface and reduces both  $\gamma_{wo}$  and  $\gamma_{wc}$ . (c) Further increasing surfactant concentration in (b) does not increasing the cleaning ability. Nevertheless the capacity is higher due to oil-micelles stabilized in water.

#### 3.2 Adsorption and surface tension

The  $\gamma_w - c$  relation in Figure 3.2 indicates that  $\gamma_w$  decreases with higher surfactant coverage at the water-air interface. This phenomenon can be explained by the thermodynamics of surface adsorption. Consider a bulk closed system, the internal energy consists of the contribution from entropy, external pressure-volume work and chemical potential of the species. If interfaces are present in the system, the surface energy should also be considered. The internal energy with all aforementioned contributions is expressed as:

$$U = \underbrace{TS}_{\text{entropy}} - \underbrace{PV}_{\text{work}} + \underbrace{\gamma A}_{\text{surface energy}} + \underbrace{\sum_{i} \mu_{i} n_{i}}_{\text{chemical energy}}$$
(3.2)

Where *T* is temperature, *S* is entropy, *P* is pressure, *V* is volume,  $\gamma$  is surface tension, *A* is surface area,  $\mu_i$  and  $n_i$  are chemical potential and amount of specie i, respectively. The intrinsic properties of *U* are *T*, *P*,  $\gamma$ , and  $\mu_i$ , and the extrinsic properties (natural variables) are *S*, *V*, *A* and  $n_i$ .<sup>3</sup> The differential form of *U* with the extrinsic properties is:

$$dU = TdS - PdV + \gamma dA + \sum_{i} \mu_{i} dn_{i}$$
(3.3)

Yet the total differential of *U* is:

$$dU = TdS + SdT - PdV - VdP + \gamma dA + Ad\gamma + \sum_{i} \mu_{i} dn_{i} + \sum_{i} n_{i} d\mu_{i}$$
(3.4)

In our system, we set both *P* and *V* to be constant. By comparing Equations 3.3 and 3.4, we have:

$$SdT + Ad\gamma + \sum_{i} n_i d\mu_i = 0$$
(3.5)

This is the Gibbs (2D) adsorption equation,<sup>4</sup> which is the 2D analog of the Gibbs Duhem equation. The Gibbs adsorption equation states the interplay between the internal properties of the system. At const T, the surface tension is related to the surface adsorption density:

$$d\gamma = -\sum_{i} \frac{n_i}{A} d\mu_i = -\sum_{i} \Gamma_i d\mu_i$$
(3.6)

where  $\Gamma_i$  is the (excess) surface adsorption density for specie i compared with the bulk solution. The 2D adsorption assumption is valid when the adsorption layer thickness is much smaller than the characteristic size of the system (i.e. the surfactants at the water-air interface). The change of  $\mu_i$  can be derived from the thermodynamics of ideal mixtures:

$$d\mu_i = RTd\ln a_i = RTd\ln x_i \tag{3.7}$$

where  $a_i$  is the activity of specie i, and  $x_i$  is the molar fraction of i. We assume  $a_i \approx x_i$  under the ideal solution assumption. Therefore the surface adsorption density  $\Gamma_i$  is written as:

$$\Gamma_i = \frac{n_i}{A} = -\frac{x_i}{RT} \frac{\partial \gamma}{\partial x_i} = -\frac{1}{RT} \frac{\partial \gamma}{\partial \ln x_i}$$
(3.8)

 $\frac{\partial \gamma}{\partial \ln x_i}$  behaves differently depending on the solute:

• Hydrophilic solute: i.e. hydrated ions (Na<sup>+</sup>, Cl<sup>-</sup>, etc)

The hydrophilic solute has lower free energy when immersed in the bulk solution compared with the surface. Therefore  $\Gamma_i < 0$  and as a result  $\gamma_w$  increases with increasing  $x_i$ .

• Amphiphilic molecule: i.e. surfactants discussed here

As discussed previously, the amphiphilic molecules tends to stay at the interface. Therefore  $\Gamma_i > 0$  and the surface tension  $\gamma_w$  decreases with adding salts.

The comparison between the two types of solutes is shown in Figure 3.4. The increase of  $\gamma_w$  due to addition of hydrophilic solutes is usually much smaller than that induced by surfactants.

The adsorption density close to  $c_{\text{CMC}}$  can be determined by plotting the slope of  $\partial \gamma / \partial \ln x_i$ when  $c \approx c_{\text{CMC}}$  (see Figure 3.2) Since  $\Gamma_i = n_i / A$ , by knowing the surface area, we can estimate the size of the amphiphilic molecule.

Figure 3.4: Change of surface tension as a function of  $x_i$  for different solutes.

### 3.3 Emulsion

One application of surfactants is to stabilize immiscible liquids to form a emulsion. We know that phase separation occurs spontaneously between pure water and oil, even after rigorous mixing. However by adding surfactants and mixing, the oil phase splits into microscopic droplets that are stabilized in water (emulsion). By mixing and forming emulsion, the interfacial area change  $\Delta A > 0$ , the free energy of mixing the two phases is then:

$$\Delta G_{\rm mix} = \Delta H - T\Delta S = \gamma_{\rm ow} \underbrace{\Delta A}_{>0} - T \underbrace{\Delta S}_{>0}$$
(3.9)

Although  $\gamma_{ow}$  is reduced by adding surfactants,  $\Delta G_{mix}$  is still dominated by the surface energy, and usually positive. As a result, the mixing and forming emulsion is *always* thermodynamically unfavored.

However we normally observe that the emulsion is *kinetically* stable over a long period of time. The kinetic stability comes from the potential barrier of repulsive forces (usually electrostatic) in the system, when the barrier height is much larger than thermal activation energy (remember at 300 K,  $kT \approx 26$  meV). As can be expected, by increasing temperature or reducing the repulsive forces in the emulsion, the stability is reduced and phase separation occurs again. The detailed theory for the kinetic stability of colloidal solution will be discussed in Lecture 13.
